Preface

The work reported herein was conducted for the U.S. Army Engineer District, New Orleans (USAEDNO). Funding for this project was provided through the USAEDNO by U.S. Environmental Protection Agency (EPA), Region 6.

This report is the second in a multiphase project. The first report, "Land farming bioremediation treatability studies for the Popile, Inc., Site, El Dorado, Arkansas," detailed a study conducted to evaluate contaminant degradation at a microcosm-scale level. This report details work conducted to evaluate design information applicable to the full-scale remediation of the process area soil from the Popile site.

This report was prepared by Messrs. Lance Hansen, Michael Channell, David Ringelberg, and Scott Waisner, Dr. Herb Frederickson, and Ms. Catherine Nestler, Environmental Restoration Branch (ERB), Environmental Laboratory (EL), U.S. Army Engineer Research and Development Center (ERDC), Vicksburg, MS. Chemical analyses were performed by the Environmental Chemistry Branch, ERDC. Physical analyses were performed by the Geotechnical Laboratory, ERDC. We gratefully acknowledge the special assistance provided by Messrs. Karl Konecny and Fred Ragan, EL, sampling assistance provided by Messrs. Demetrick Banks and Samuel Tucker, and Ms. Lynn Vaughn, EL, as well as the participation of students of the Science and Engineering Apprentice Program, George Washington University.

This study was conducted at ERDC under the direct supervision of Mr. Daniel E. Averett, Chief, ERB, and Mr. Norman R. Francingues, Chief, Environmental Engineering Division, and under the general supervision of Dr. John Keeley, Director, EL.

At the time of publication of this report, Dr. James R. Houston was Director of ERDC, and COL James S. Weller, EN, was Commander.

This report should be cited as follows:

1 Introduction

Site History

The Popile, Inc., site is a former wood-treatment facility located in El Dorado, AR. The primary contaminants found at the site include pentachlorophenol (PCP) and creosote compounds associated with wood treatment, including polycyclic aromatic hydrocarbons (PAH). The site was purchased by Popile, Inc. Wood-treatment operations ceased in July 1982. In 1984, Popile consolidated three impoundment ponds into one. This closure activity was administered by the Arkansas Department of Pollution Control and Ecology. In 1988 and 1989, an Environmental Protection Agency (EPA) field investigation revealed contaminated soils, sludges, and groundwater at the site. EPA determined that an emergency removal action was necessary. This was conducted from September 1990 to August 1991. The emergency action consisted of modifying the site drainage, placing and seeding topsoil, and solidifying and placing sludges into an onsite, soil-holding cell.

The EPA's design contractor, Camp, Dresser and McKee, Federal Programs, was tasked with the development of the Remedial Investigation/Feasibility Study for the Popile site. The remedy that was approved involves the excavation and treatment of approximately 126,142.5 cu m (165,000 cu yd) of contaminated soils and sludges in onsite land treatment units (LTUs). Indigenous microorganisms were expected to break down the target contaminants to less harmful and less mobile constituents.

Two types of contaminated soils exist on the site. The first is the soil-holding-cell material, consisting of soils stabilized with rice hulls and fly ash (pH approximately 10) under previous emergency remedial activities. The second is the process area which consists of soils that were contaminated by spills, leaks, and open air drying during wood-treatment activities. Results of Phase I indicated it unlikely that material from the soil cell could be successfully treated using landfarming techniques. Therefore, the Phase II evaluation was conducted on contaminated material only from the process area.

Chapter 1 Introduction 1

Objectives of Study

The objectives of the Phase II study were to:

- a. Determine if the treatment goals specified in the Record of Decision (ROD) are achievable for the process area soil through land farming technology (these goals are: 5 ppm benzo(a)pyrene (BaP) equivalents and 3 ppm PCP).
- b. Evaluate the contaminant degradation kinetics associated with the landfarming treatment.
- c. Evaluate the leaching potential of the treated soil.

2 Chapter 1 Introduction

2 Literature Review

Contaminants of Interest

Pentachlorophenol (PCP)

Because of its potency as a biocide and its persistence in the environment, PCP has been widely used as an insecticide, fungicide, and disinfectant. It's now a restricted-use pesticide, and although it's no longer available for residential use, PCP is still a common component of industrial wood preservative for power line poles, railroad ties, and fence posts (Appendix A). PCP is not a particularly volatile chemical. It will undergo photolysis, especially in surface water. It is relatively hydrophobic and tends to adsorb onto soil particles, but the strength of the bond depends on the pH of the soil. At lower pH, it may dissociate into the water, leaching through contaminated soil and entering the groundwater in that manner. PCP and several of its breakdown intermediates (i.e., tetrachloro-*p*-hydroquinone) are considered possible carcinogens (ATSDR 1994).

Polycyclic aromatic hydrocarbons (PAH)

Polycyclic aromatic hydrocarbons are multiringed, organic compounds, characteristically nonpolar, neutral, and hydrophobic. PAHs have two or more fused benzene rings in a linear, stepped, or cluster arrangement (Appendix A). PAHs occur naturally as components of incompletely burned fossil fuels and they are also manufactured. A few of these are used in medicines, dyes, and pesticides, but most are found in coal tar, roofing tar, and creosote, a commonly used wood preservative. The Popile site is contaminated with high concentrations of a wide range of PAHs, including the recalcitrant, higher molecular weight PAHs. Some lower molecular weight PAHs are volatile, readily evaporating into the air. Others will undergo photolysis. Because they are hydrophobic and neutral in charge, PAHs are strongly adsorbed into soil particles, especially clays. Park et al. (1990) studied the degradation of 14 PAHs in two soils. They found air-phase transfer (volatilization) an important means of contaminant reduction only for naphthalene and 1-methylnaphthalene (the tworing compounds). Abiotic mechanisms accounted for up to 20% of the total reduction, but only involved two- and three-ring compounds. Biotic mechanisms handled reduction of PAHs over three-ring compounds. The persistence of PAHs in the environment, coupled with their hydrophobicity, gives them a high

potential for bioaccumulation. PAHs are considered to be both mutagenic and carcinogenic (ATSDR 1995).

Benzo(a)pyrene (BaP) equivalents

Different PAHs each have different toxic potencies that vary widely. Some PAHs appear to be nontoxic, while others have been classified as probable or possible carcinogens. BaP is often used as an indicator for risk assessment of human exposure, because it is highly carcinogenic, persistent in the environment, and is toxicologically well understood. This level of knowledge doesn't exist for most of the other PAH compounds.

Because PAHs generally occur in mixtures, toxic equivalency factors (TEF) were proposed. These factors were similar to those used in the risk assessment of mixtures of polychlorinated biphenyls (PCB). The U.S. Environmental Protection Agency (USEPA) took the first step in 1984 by separating the PAHs into carcinogenic and noncarcinogenic compounds. All of the PAHs were rated, using BaP as a reference and giving it a value of 1.00. However, this method led to an overestimation of exposure risk since the carcinogenicity of the compounds was unknown. In an attempt to overcome this liability, Nisbet and LaGoy (1992) developed a new method based on the response of the compounds while testing one, or more, PAHs concurrently with BaP in the same assay system (usually lung or skin cell carcinoma). BaP remained the reference carcinogen assigned the value of 1.00. Sixteen other PAHs were ranked in comparison to BaP carcinogenicity.

This system was tested by Petry, Schmid, and Shlatter (1996) who assessed the health risk of PAHs to coke plant workers. There are drawbacks to any system that uses equivalency factors. The uncertainties in this case arise primarily from dealing with inconsistent mixtures. Carcinogenic potency could be affected by differences in bioavailability, a competition for binding sites, co-carcinogenic action, or the effects of metabolism. Nevertheless, Petry and his co-workers found that the BaP equivalents developed by Nisbet and LaGoy were valid markers for PAH health risk assessment.

Environmental risk assessment, in a slight contrast to human health risk, looks at the PAHs that usually occur in contaminated environmental systems and that have the highest TEFs (by the Nisbet and LaGoy system). This gives seven PAHs, listed in Table 1, with the highest environmental risk: benzo(a)anthracene, chrysene, benzo(b)fluoranthene, benzo(k)fluoranthene, benzo(a)pyrene, indeno(1,2,3-cd)pyrene, and dibenzo(a,h)anthracene. Because BaP was stipulated in the ROD, this method was used to evaluate the effectiveness of contaminant degradation.

4 Chapter 2 Literature Review

Table 1 Toxic Equivalency Factors (TEFs) for Environmental PAHs					
Compound (abbreviation	Compound (abbreviation) TEF (after Nisbet and LaGoy 1992)				
Benzo(a)anthracene	(BAANTHR)	0.1			
Chrysene	(CHRYSE)	0.01			
Benzo(b)fluoranthene	(BBFLANT)	0.1			
Benzo(k)fluoranthene	(BKFLANT)	0.1			
Benzo(a)pyrene	(BAP)	1.0			
Indeno(1,2,3-c,d)pyrene	(I123PYR)	0.1			
Dibenzo(a,h,)anthracene	(DBAHANT)	1.0			

Landfarming

According to the Federal Remediation Technologies Roundtable (1998), there are several EPA-accepted processess to remediate the waste from wood-treatment sites. These treatment technologies include thermal desorption, incineration, landfarming, and bioremediation. The choice of remediation technology is based on the concentration of the contaminants, cost, intended use of the land after remediation, and other factors. With the current "land ban" on hazardous waste disposal and the restrictive regulations on incineration, landfarming as a way of treating waste has become increasingly attractive (USEPA 1995) and was selected as the technology to remediate the Popile site.

Generally, during landfarming, the degradation process will destroy the organic contaminants in place without the high cost of excavation and material handling. The release of volatile contaminants into the air is minimized. The site is monitored on a continuous basis so the potential for hazardous waste leakage is reduced. The costs associated with landfarming are generally much lower than ex situ treatment alternatives. In most instances, the treatment is accepted by the community and the site can be put to other uses when the treatment is complete (USEPA 1995). This last point has become increasingly important in the 1990's with the EPA Superfund policy changes towards "brownfields" development.

Successful bioremediation through landfarming has to meet these three criteria:

- a. There must be a loss of the contaminant over time.
- b. There must be a demonstrated ability of the indigenous microorganisms to degrade the contaminant over time.
- c. There must be evidence that this biodegradation potential is expressed in the field.

Landfarming technology remediates contaminated soil in an aboveground system using conventional soil mangement practices. The contaminant is converted to a less toxic or nontoxic form either abiotically (ex. photolysis) or biotically, through the metabolism of the indigenous microbial population

(Golueke and Diaz 1989, Harmsen 1991). Landfarming as a form of applied bioremediation is the cultivation of contaminated soil at properly engineered sites to stimulate the naturally ocurring microorganisms to degrade the organic contaminants. The landfarming operational goal, then, is to manage the parameters that optimize conditions for microbial activity. Typically, these include the soil carbon to nitrogen ratio, soil moisture, pH and oxygen content, temperature and cultivation frequency. The type of soil being remediated, and the type and concentration of contaminant, are also factors that shape landfarming management. The rate of biodegradation can be monitored through the rate of CO₂ production and release and by chemical analysis of the hydrocarbons (King 1992, Reisinger 1995).

When weighing treatment options, however, the disadvantages of landfarming must be considered. It is land and management intensive. An improperly designed system could lead to adverse environmental effects such as groundwater contamination. Air and odor emissions may also be hazardous, or simply a nuisance. Airborne particles could be a problem. Finally, landfarming is not suitable for all kinds of hazardous wastes (e.g., radioactive wastes).

Because landfarming involves a biological system, the limits to this biological system are also limits to landfarming. The bacteria found most often associated with successful landfarming are either obligate or facultative aerobes, therefore the soil oxygen content is an important parameter. The tilling (cultivation) frequency is an important aspect of maintaining the oxygen level as well as exposing the bacteria to renewed sources of the contaminant. Most of the microbial communities involved with landfarming are mesophilic. The pH range that will support their growth is relatively narrow, usually in the 6.0 to 7.5 range. They prefer a moisture level that is 30 to 90 percent of the water-holding capacity of the soil. Also, most hazardous wastes are nutrient deficient. Some kinds of wastes are lethal (heavy metals), or inhibitory (in high concentrations) to the microbial communities. The degradation process should be studied in the laboratory to determine that it doesn't produce intermediates or end products that are as harmful as the contaminants being remediated. However, all of these limitations to landfarming can be overcome, with the exception of the presence of heavy metals and/or radioisotopes in the contaminant mixture (Golueke and Diaz 1989, USEPA 1995).

Landfarming of soils contaminated with PAHs and PCP has been studied several times but not usually at the concentrations found at the Popile site. The GRACE DaramendTM SITE evaluation report (USEPA 1996) cites initial concentrations of 352 mg/kg total of chlorinated phenols (TCP) and 1,710 mg/kg of total PAH reduced in 254 days to 43mg/kg and 98 mg/kg, respectively. Clark and Michael (1996) used "enhanced" landfarming to achieve degradation goals in 15 months. The study of "aged" PCP (McGinnis et al. 1994) found that concentrations up to 300 mg/kg weren't inhibitory to the bacteria if soil phosphorus and oxygen concentration levels were maintained. Hurst et al. (1997) have found microbial activity in soil containing up to 500 mg/kg PCP. Again, the oxygen concentration in the soil was a significant factor in successful degradation, although anaerobic degradation of PCP has been reported (Frisbie and Nies 1997).

6 Chapter 2 Literature Review

3 Experimental Design

Land Treatment Units

LTU Design

The pilot-scale LTUs were built to simulate the full-scale LTU design being implemented onsite at Popile. The pilot-study LTU consisted of a bottom impermeable liner, a sand bed leachate collection system, and hard standing walls to withstand impact from cultivation. To provide environmental security for this study, a secondary containment cell was constructed similar in concept to a landfill liner (modified American Society for Testing and Materials (ASTM) D-1973-91 (ASTM 1991)). This secondary system was backfilled with clean sand to provide a base for the LTUs. Figure 1 illustrates the design of the primary and secondary containment systems and the leachate collection system. Actual construction is shown in Figures 2 and 3 in Materials and Methods (Chapter 4).

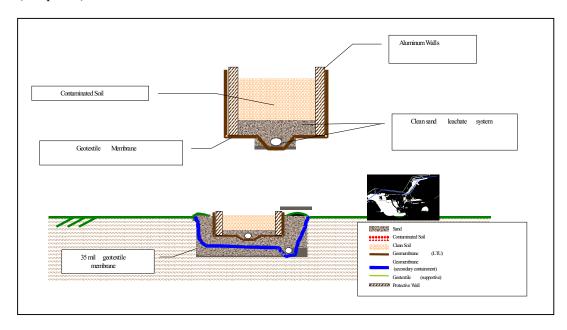

Figure 1. Design of primary and secondary containment systems

Experimental design

The study was designed to evaluate two cultivation management strategies. LTU 1 was cultivated on an oxygen dependent basis. When the oxygen concentration in the pore space was reduced to 5 percent, the lift was to be tilled. LTU 2 was cultivated on a fixed schedule, every 2 weeks, independent of the oxygen concentration.

Soil samples were taken every 2 weeks. The parameters included in the bimonthly soil analysis were contaminant concentration, nutrient concentration (total Kjeldahl nitrogen (TKN), total phosphate (TP)), total organic carbon (TOC), pH, and moisture content. Microbial biomass was evaluated intermittently throughout the study. At the initial and final sampling events, leachability, particle size distribution (PSD) and Atterberg limit tests were performed. At the initial sampling only, metal concentrations and total volatile solids were examined. The analysis schedule is shown in Table 2.

Table 2 Sample Analysis Plan			
Initial	2-week Intervals	Final	
PCP concentration	PCP concentration	PCP concentration	
PAH concentration	PAH concentration	PAH concentration	
Nutrient and TOC concentration	Nutrient and TOC concentration	Nutrient and TOC concentration	
pH	pH	pH	
Moisture content	Moisture content	Moisture content	
Leachability		Leachability	
Microbial biomass		Microbial biomass	
PSD		PSD	
Atterberg limits		Atterberg limits	
Metals			
Total volatile solids			

Metabolic Analysis

Respiration, measured by soil gas analysis, was monitored twice each week to record changes in the oxygen and carbon dioxide concentrations.

Microbial characterization of the indigenous microbiota was conducted to assess the biomass and community composition in each LTU. This analysis was performed on contaminated soil before the LTUs were loaded, soil after it was transferred to the two LTUs (Day 0), and intermittently throughout the study on Days 14, 42, 84, 126 and 168.

Abbreviations

This report uses standard abbreviations for the PAHs and analytical chemistry. The PAHs and PCP are listed in Appendix A with full name, abbreviation, and chemical structure.

4 Materials and Methods

LTU Construction

Secondary containment system

A backhoe was used to excavate a pit measuring approximately $9.14 \times 9.14 \times 0.91$ m ($30 \times 30 \times 3$ ft). It was subdivided into two sections using a row of sandbags. One side of the pit area was used for the LTUs and the other side for the leachate collection containers. The 36-mil liner, used for both sides of the pit, was molded into the corners, over the divider, and extended beyond the edge of the pit (Figure 2). The Cooley Coolguard® secondary containment liner was purchased from Colorado Lining, International.

A leachate collection system consisting of 10.2-cm (4-in.-) diameter perforated PVC pipe was placed on top of the liner and connected to a sump. This system was similar for both sides of the pit. A ½-hp sump pump was installed in each sump to move the leachate into the storage container. Next, 25.4 cm (10 in.) of washed gravel was placed in each side. A geotextile fabric was placed on top of the gravel to keep sand from filtering down and plugging up the leachate collection system. The half of the pit that supports the tanks was filled with sand and covered with another layer of the geotextile.

Primary containment system and LTUs

The primary containment leachate collection system also employed the 36-mil Cooley Coolguard[®] liner and standard ½-hp sump pumps. The LTU walls and bottom were constructed from 0.64-cm- (¼-in.-) thick aluminum sheets. Sandbags were used as structural supports, separating the two containment areas.

Figure 2. Construction of the secondary containment system

A stable base for the LTUs was formed in the second half of the pit by filling it about halfway with sand. Two sheets of aluminum 1.22×3.05 m (4×10 ft) were used for each LTU (6.10 m (20 ft) total length). The aluminum had 1.27 cm ($\frac{1}{2}$ -in.) holes drilled on 15.24-cm (6-in.) centers to allow for drainage of water from the LTU. Sandbags were used to form the support walls for the LTUs. With the walls in place, the aluminum sheets were removed and replaced with more of the 36-mil containment liner. A sump was installed at each end of the LTU with 10.16-cm (4-in.) perforated PVC pipe connected to the sump. Gravel was again placed over the leachate collection system and covered with geotextile. The bottom sheets of aluminum were replaced in each LTU and preformed aluminum walls were positioned against the sandbags to make the sides. The last step was to fill in the area around the outside of the LTUs with sand. Each completed LTU was approximately 45.72 cm deep, 1 m wide, and 6 m long (18 in. deep, 4 ft wide, and 20 ft long) (Figure 3).

Rainfall at the pilot site was monitored electronically with a Rainwise ® tipping bucket. In addition, a direct-reading rain gauge served as backup.

Water that leached through the LTUs was contained onsite and tested for presence of the contaminants on Day 14 and again on Day 168. Chemical analysis of the leachate was performed by the Environmental Chemistry Branch, U.S. Army Engineer Research and Development Center (ERDC), Vicksburg, MS. Contaminated water was treated by carbon filtration, retested and disposed of by ERDC.

10

Figure 3. Construction of primary containment system and LTUs

Sample Collection

Soil sample collection

As shown in Figure 4, each LTU was subdivided into 20 sections, each one $0.61\text{-}\times0.61\text{-}\mathrm{m}$ (2-ft × 2-ft). These were lettered "A" through "T". A sampling grid was constructed from a $0.61\text{-}\times0.61\text{-}\mathrm{m}$ (2- × 2-ft) section of plexiglass drilled with 36 equidistant holes for the soil corer. At each sampling interval, five randomly located cores were collected from each of the 20 sections. The five soil cores for each single grid were combined in a 950-cc amber jar and manually homogenized into a single sample. A random number generating computer program selected 7 of these 20 grids for analysis. The remaining 13 samples were archived at 4 °C in their original collection jar. The stainless steel corer (1.91 × 48.26 cm (3/4 × 19 in.)) was purchased from Forestry Suppliers, Inc.

Respiration analysis

Dry wells, installed in each LTU for respiration analysis, were designed at WES and made by PSI, Inc., Jackson, MS. They were constructed from a 15.24-cm (6-in.) upper ring and cap of PVC superimposed on a 30.48-cm (12-in.) vertical dry well made of standard 5.08-cm (2-in.) slotted PVC (Figure 5). The cap was equipped with a three-way plastic stopcock purchased from Cole-Parmer.

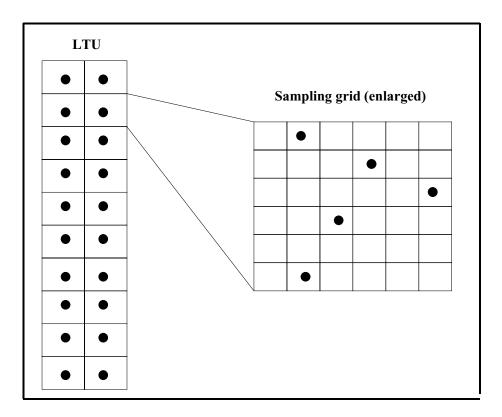

Figure 4. LTU random sampling grid

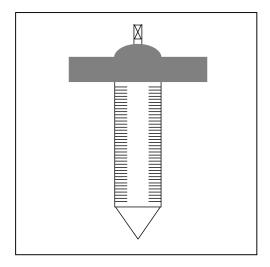

Figure 5. Conceptual dry well design

Cultivation

LTU 2, only, was tilled after soil sampling. When necessary, water and/or nutrients were added to the unit prior to tilling. The surface of LTU 1 was raked lightly after sampling, to fill in the sample holes. LTU 2 was cultivated to a depth of 30.48 cm (12 in.) with a rear-tine rotary cultivator.

Sample Analysis

Physical analysis

Atterberg limit analysis and particle size distribution (PSD) were used to evaluate the physical structure of both the untreated and treated soils. The Atterberg limit test was performed by the Geotechnical Laboratory, ERDC, according to Corps of Engineers laboratory testing manual standard procedures. Particle size distribution was measured on a Coulter LS100Q particle counter according to instrument protocol. Soil moisture was analyzed on a Denver Instrument IR-100 moisture analyzer and validated by oven-drying at 105 °C for 24 hr.

Leachability

Two leachability tests were conducted, the sequential batch leaching test (SBLT) and the synthetic precipitate leaching procedure (SPLP). The SBLT consists of four repeat extractions of the same sample using distilled-deionized water in a 4:1 (water:soil) ratio. The slurry is tumbled for 24 hr, centrifuged, filtered, and the water fraction analyzed for the contaminants. The SPLP was performed according to SW846, EPA Method 1312, and consists of a single extraction using a dilute acid solution. Maximum extractant concentration for a known solid-phase concentration is controlled by equilibrium partitioning. This can be determined from the single-point analyses in the SPLP or the SBLT. The SBLT is thought to be more aggresive due to the fact that the water has no ions in it and is looking to absorb ions and come to equilibrium with the sample. This information is useful and has regulatory acceptance, however it is incomplete because it precludes analysis of residual contaminant in the solid matrix which may be eluted under repeated or changing equilibrium conditions such as are observed in repeat rain events. To comply with necessary regulatory requirements and meet the needs of the project sponsor, both leachability tests were conducted with five replicates at Day 14 and Day 168.

Chemical analysis

Contaminant concentrations, metals, nitrogen, phophate, and total organic carbon analyses were performed by the Environmental Chemistry Branch, ERDC, on both treated and untreated soil. PAH and PCP concentrations were determined using SW846 EPA Method 8270c for gas chromatography/mass spectrometry (GC/MS) after extraction by Method 3540c. Total organic carbon samples were analyzed on a Zellweger Analytic TOC analyzer, according to instrument specifications. The nitrogen and phosphate analysis was performed using the Lachat 8000 Flow Injection Analyzer (FIA). The preparation methods were modified versions of EPA-600/4-79-020 (1983 revision), 365.1 and 351.2, respectively. Metals and total volatile solids were determined according to standard methods (SW 846). Soil pH was determined for a soil-distilled water slurry (1:1, wt/vol) using a Cole-Parmer® pH meter.

Metabolic analysis

Gas analysis in the landfarming units was accomplished using an LMSx Multigas Analyzer[®] from Columbus Instruments. Oxygen, carbon dioxide, and methane concentrations in the soil were monitored. The drywells were labeled and centered in each LTU grid section. Following gas sampling, the drywells were lifted from LTU 2, soil samples were taken, the soil was tilled, and the drywells were reinserted in the appropriate section. The drywells remained in place in LTU 1.

Microbial biomass was determined at Days 0, 14, 42, 84, 126, and 168 during the study. Two grams (wet weight) of soil /sample were subjected to an organic solvent extraction to quantitatively recover bacterial membrane lipid biomarkers (ester-linked phospholipid fatty acids or PLFA) as outlined by White and Ringelberg (1998).

Data Analysis

Chemical data

The chemical analytical data were reduced to develop average sums of the concentrations of total PAH, individual PAH compounds, and total PCP. To calculate the magnitude of reduction and the rate of degradation of these contaminants, the initial and final concentration values were used. Zero order (concentration independent) removal rates were assumed due to the high concentrations of the contaminants (Shane 1994). Contaminant concentration and physical data values are significant (n = 7) at the 95% confidence level.

The total % PAH and total % PCP reductions were calculated using Equation 1:

%
$$R_{contaminant} = ([C_{initial}] - [C_{final}]) / [C_{initial}] \times 100$$
 (1)

where

%R_{contaminant} = removal of contaminant, % of initial

[C_{initial}] = average initial contaminant concentration in the LTU

 $[C_{final}]$ = average final contaminant concentration in the LTU

The rate of elimination (k) of the contaminants was calculated as a concentration-dependent, zero-order reaction

$$k=-dC/dt$$
 (2)

$$k = -(C_1 - C_2)/(t_2 - t_1)$$
(3)

where

k = concentration change / time

 C_1 = concentration at Day 0

 C_2 = concentration at Day 168

 $t_1 = 0$

 $t_2 = 168$

The time required to acheive the ROD goals can be calculated by substituting the goal (5 ppm for PAH) for the final concentration(C_2), and solving for " t_2 ."

Because $t_1 = 0$, this simplifies to,

$$T_2 = (C_2 - C_1)/k \tag{4}$$

Microbiological data

The microbiological data was subjected to a Tukey hierarchal significant difference (HSD) to determine if there was a significance to the differences between the data for the two LTUs, taking into account that more than two samples were taken (Ringelberg et al. 1989). The hierarchal cluster analysis was used because there was no *a priori* hypothesis tested. It attempts to minimize the the sum of squares of any two clusters found at each step of an algorithim. It was used to try to determine if a significant relationship existed between sets of data for the two LTUs (Ringelberg et al. 1997).

5 Results and Discussion

Physical Characteristics of the Popile Soil

Atterberg limits

The Atterberg limits, Table 3, are the values where the moisture content of the soil will allow the soil to change state from a solid to a semisolid, to a plastic, and then a liquid. These limits also establish the soil type. LTU 1 initially had a liquid limit of 23% and a plastic limit of 17%. The soil type was designated clay/clay-silt. LTU 2 demonstrated a liquid limit of 26%, a plastic limit of 17%, and was designated per Corps of Engineers classification as a clay soil.

Table 3 Atterberg Limits				
LTU 1 LTU 2				.TU 2
Characteristic	Day 0	Day 168	Day 0	Day 168
Liquid limit	23	24	26	23
Plastic limit	17	19	17	19
Plasticity index	6	5	10	4
Soil type	clay/silt	silt	clay	silt

Particle size distribution (PSD)

The initial PSD supported the results of the initial Atterberg limits (Appendix B). Based on the Corps of Engineers particle size classification, soil typ is indicated by the Atterberg Limits. The text indicates that the same conclusion for soil classification is achieved by both methods: LTU 1 consisted of 68% fines (clay/silt), and LTU 2 consisted of 76% fines (Figure 6). At Day 168, these values were not significantly different.

Dust is a drawback to landfarming that can be countered by keeping the soil surface moist or covered, for example with plants. Dust production results in a loss of fines, the clay/silt fraction, from the land-treatment area.

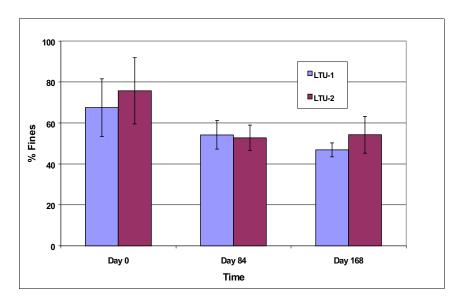

Figure 6. Particle size distribution

Although LTU 1 was cultivated only once (for nutrient homogenization), and LTU 2 was cultivated 17 times throughout the 168-day study, this does not appear to have had a significant impact on the physical structure of the soil.

Soil moisture and field moisture capacity

The field moisture capacity (FMC), as defined by the U.S. Departemnt of Agriculture – Natural Resources Conservation Service, is the moisture content of the soil, expressed as a percentage of the ovendry weight, after the gravitational, or free, water has drained away. More simply, this is the moisture content 2 to 3 days after a soaking rain. It is also known as the normal field capacity, the normal moisture capacity, or the capillary capacity. The Popile soil delivered to the pilot facility had an FMC of 23%. In general, landfarming as bioremediation requires that the moisture content be maintained between 30 and 90% of the FMC to sustain microbial growth. For Popile soil, this correlates to 6.9 to 20.7% moisture. At Day 0, the moisture content was 15 and 14% for LTU 1 and LTU 2. respectively, putting them within the required moisture boundaries. The statement of work (SOW) denoted maintaining the moisture content between 50 and 80% of FMC, translating to a soil moisture content between 11.5% and 18.4% (Figures 7 and 8). The FMC was retested at Day 112 (after a soaking rain). At this time, the LTUs showed an increase in capacity, to 28% for LTU 1 and 30% for LTU 2 (an increase of 21% and 30% for LTU 1 and 2, respectively). Maintaining 50 to 80% FMC, this correlates to a soil moisture content of 14 to 22% for LTU 1 and 15 to 24% for LTU 2. When soil moisture content fell below the 50% FMC minimum, water was added to bring the moisture content up to 80% of the FMC. Maintaining the soil moisture level at over 50% FMC proved problematic. The high concentration of tightly sorbed hydrophobic hydrocarbons repelled moisture (Luthy et al. 1997) in the soil. High temperatures and winds accelerated the evaporative losses.

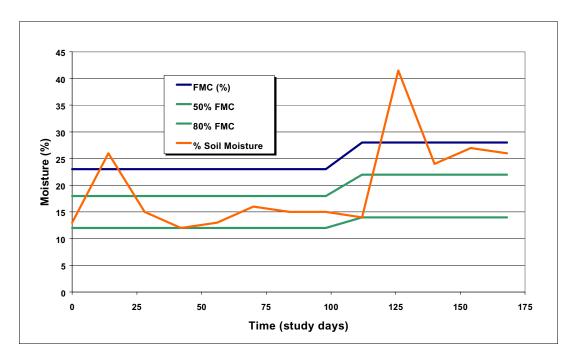

Figure 7. LTU 1. Relationship between soil moisture and field moisture capacity

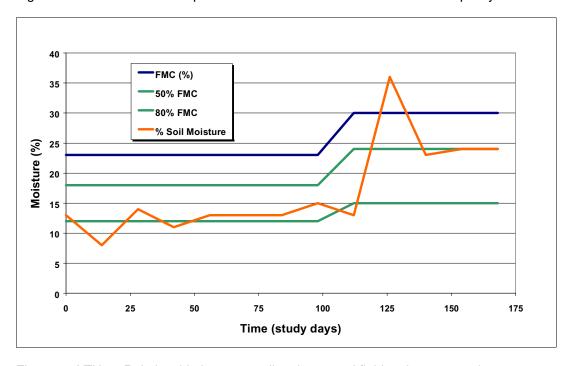

Figure 8. LTU 2. Relationship between soil moisture and field moisture capacity

LTU leaching

Natural rain events and watering to maintain the soil moisture resulted in leachate from the LTUs. Table 4 shows the results of the initial and final leachate analysis. The primary contaminant of the leachate was PCP.

Table 4 Concentrations of Contaminants in LTU Leachate			
	Conce	entration, mg/l	
Contaminant	Day 14	Day 168	
PCP	197.0		
Phenol	3.13		
2-methyl phenol	1.82 (estimated)		
4-methyl phenol	5.3		
Naphthalene	1.0 (estimated)		
Dibenzofuran	1.28 (estimated)		
Note: Blank spaces indicate	values below detection limit.		

Leachability test

The results of the SBLT leaching test in LTU 1 at Day 14 and Day 168 are shown in Figure 9. The SBLT for LTU 1 on Day 168 showed that only 7.9% of the available PCP was leached from the sample during the test. As time increases, the concentration of PCP decreases. The SBLT indicates that probably less than 10% of the PCP is in a form available for microbial degradation. LTU 2 performed in a similar manner, as shown in Figure 10. In both LTUs, less than 0.5% of the PAHs leached from the samples.

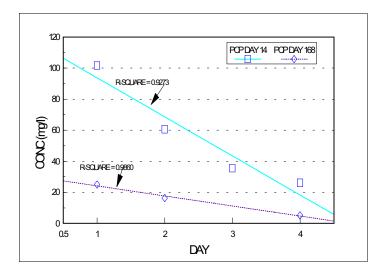

Figure 9. LTU 1. Results of SBLT

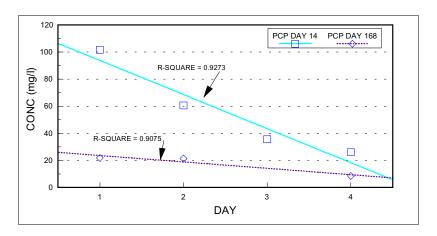

Figure 10. LTU 2. Results of SBLT

The results of the SPLP are shown in Table 5. Both LTU 1 and LTU 2 demonstrated a dramatic decrease in PCP leachability from the beginning to the end of the study. Under these slightly acidic conditions, less than 5% of the PCP was leached from the soil during the SPLP. The PAHs were below detection limits.

Table 5 Synthetic Precipitate Leaching Procedure Test Results				
		Day 168		
Compound	Day 0	LTU 1	LTU 2	
Pentachlorophenol	34.4±3.0	3.63±0.67	4.71±0.81	
Naphthalene	5.8±0.5	0.0	0.0	

Chemical Characteristics of the Popile Soil

Nutrients and TOC

A typical soil should have total nitrogen values around 1,500 ppm and total phosphate around 400 ppm (Lyon, Buckman, and Brady 1952). As expected from the landfarming literature (Dibble and Bartha 1979, Golueke and Diaz 1989), the nitrogen in the Popile soil was low (Table 6). The target concentrations for C:N:P of 100:10:1 would correlate to 28,000:2,800:280 in the Popile soil. This initial nitrogen, then, is an order of magnitude lower than our optimal targets. Nitrogen, as NH₄, was added in aqueous form to increase the nitrogen concentration in the system. The aqueous addition was problematic due to the high hydrophobic hydrocarbon concentrations. Solid nitrogen addition was attempted with some success when it coincided with a natural rain event. Phosphate was not limiting in this system. Nitrogen may have been a limiting nutrient. Following nitrogen (fertilizer) addition, there was a burst of microbial growth and CO₂ production.

Table 6 Initial Nutrient Analysis		
Nutrient	Concentration (mg/kg)	
Total Kejldahl Nitrogen (TKN)	158.5±18.13	
NO ₂ -N	1.88 *estimated value

рΗ

Soil pH affects the contaminant chemistry and interactions with the soil particles. The initial soil pH for both LTUs was 9. This initial pH immediately began decreasing (7.4 at Day 84). However, by Day 168 the pH had returned to 8. Figures 11 and 12 illustrate the interaction between pH and PCP in LTU 1 and 2, respectively. As outlined by Lee et al. (1990), at neutral pH, PCP can be found as both a phenolate anion and in its neutral form. Below pH 7, the neutral species adsorbs to the soil with increasing strength as the pH drops and/or the organic carbon increases. Above pH 7, the ion adsorbs to the soil particles and also can form complexes with soil metals. With Popile soil, we have a situation in which the pH is above 7 at the beginning, the organic carbon content is high (Table 6), and there is a high iron content (Table 7). The PCP possibly was initially complexed to the iron and adsorbed to the organic components of the soil. As the pH decreased, this PCP was released back into the soil, becoming available for degradation and, thus, appearing to increase in concentration.

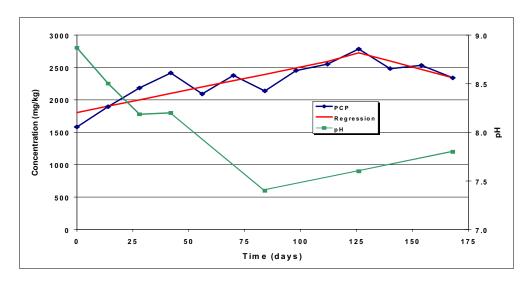

Figure 11. LTU 1. Relationship between soil pH and PCP concentration

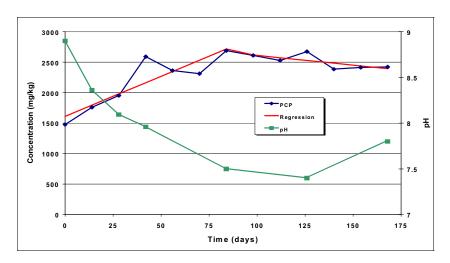

Figure 12. LTU 2. Relationship between soil pH and PCP concentration

Contaminants

Figure 13 illustrates the general decrease in the concentration of PAHs in LTU 1 and 2. LTU 2 showed a greater reduction in the contaminant. No decrease in PCP concentration was seen in either LTU.

When the PAH reduction is examined by individual compound (Figures 14 and 15, and Appendix A), decreases are evident in both LTUs for naphthalene and 2-methylnaphthalene (2-ring compounds). Removal of the 2-ring PAHs generally occurs through a combination of physical (ex. volatilization) and biological processes. LTU 1 also shows a slight decrease in acenaphthalylene, fluoranthene, and phenanthrene (2- and 3-ring compounds). Removal of 3-ring compounds is generally accepted as evidence of biological degradation of PAH due to the low volatility of these compounds.

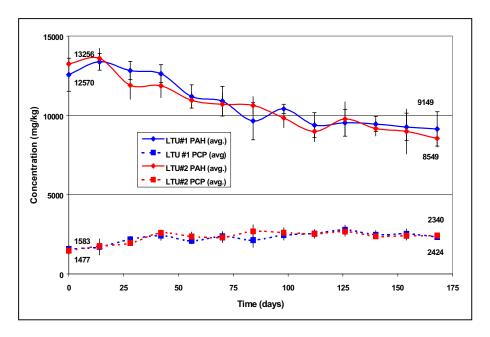

Figure 13. A comparison of PAH and PCP concentrations in LTU 1 and 2

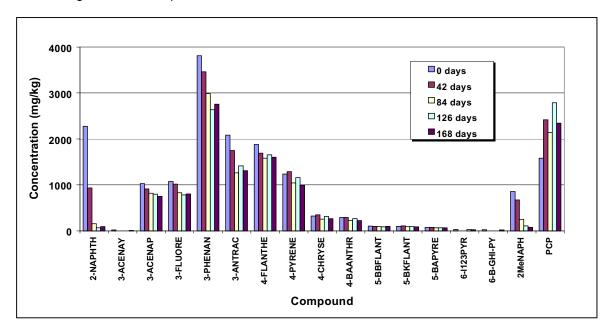

Figure 14. LTU 1. A comparison of PAH and PCP concentrations. The number of rings composing each compound is indicated at beginning of name

In LTU 2, these decreases in concentration of the 2- and 3-ring compounds are greater and include anthracene (3-ring). The increase in PCP concentration is more marked in LTU 2, especially between Day 0 and Day 84, the same period in which the pH was decreasing.

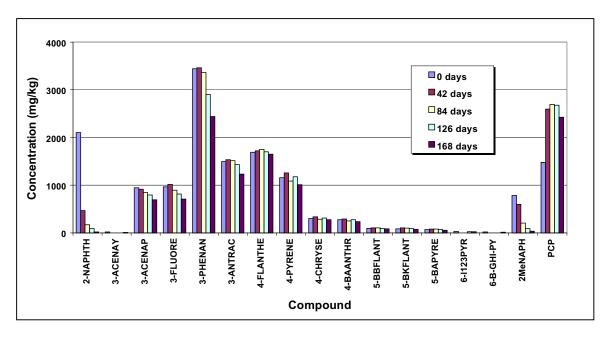

Figure 15. LTU 2. A comparison of PAH and PCP concentrations. The number of rings Composing each compound is indicated at the beginning of each name

BaP equivalents

When the BaP equivalents are calculated (Figure 16), LTU 2 demonstrated a greater overall decrease.

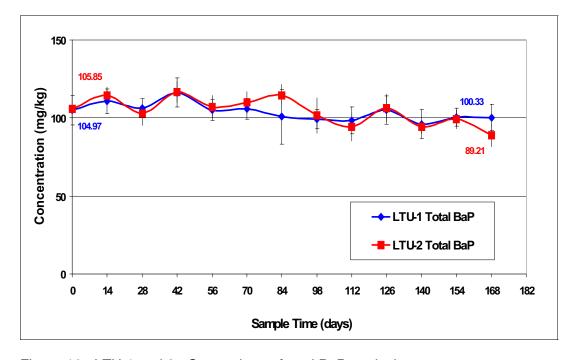

Figure 16. LTU 1 and 2. Comparison of total BaP equivalents

Figures 17 and 18 examine the BaP-equivalent PAH compounds in each LTU. LTU 2 shows a more pronounced decrease in benzo(a)pyrene.

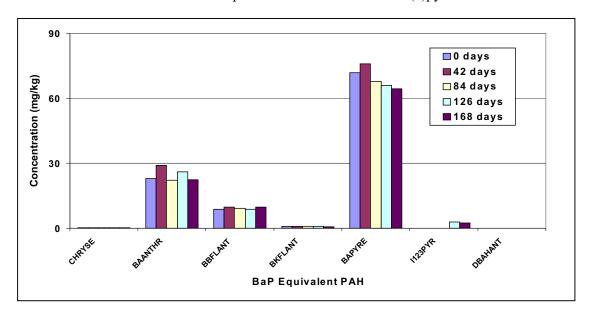

Figure 17. LTU 1. The BaP-equivalent compounds

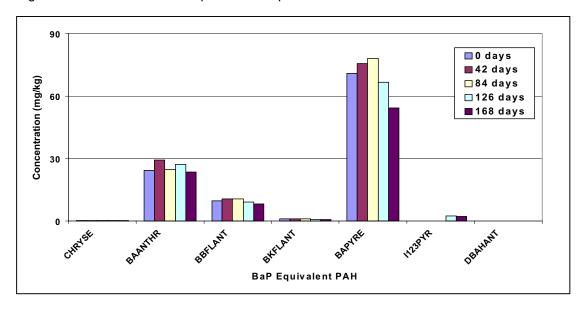

Figure 18. LTU 2. The BaP-equivalent compounds.

Metabolic Characteristics of Popile Soil

Biomass

As shown in Table 8, Figure 19, and Figure 20, viable biomass increased in both LTUs over time. The greatest increase in LTU 1 occurred between Days 42

and 84 . In LTU 2, the greatest increase occurred between Days 84 and 126. Biomass estimates at the endpoint, 168 Days, averaged 4.5×10^8 and 5.5×10^8 cells/g in LTUs 1 and 2, respectively, representing a 2 and 4-fold increase over the Day 0 values (Table 8). However, the 2-fold increase in LTU 1 was insignificant (Tukey HSD, p<0.05) whereas the 4-fold increase in LTU 2 was significant (Days 84 through 168 versus Day 0). Biomass differences between LTUs, at common time points, were also insignificant at all time points except Day 126. At this point, the biomass in LTU 2 was significantly greater than that in LTU 1. Viable microbial biomass estimates for the original delivered soil and LTU Day 0 soil were not significantly different.

Community composition

No significant differences existed between the major bacterial classifications examined. An important observation was the magnitude of the coefficients of variation (CV) at the beginning of the study and the steady decline in these magnitudes over time (Table 9). This result indicates that, although the contaminant distribution may have been homogeneous at Day 0, microbial community distribution was not. Spatial heterogeneity in microbial biomass and community composition was apparent in the original delivered soil and in both LTUs. The values shown represent the average of all replicate sample (n = 7) per time point per LTU.

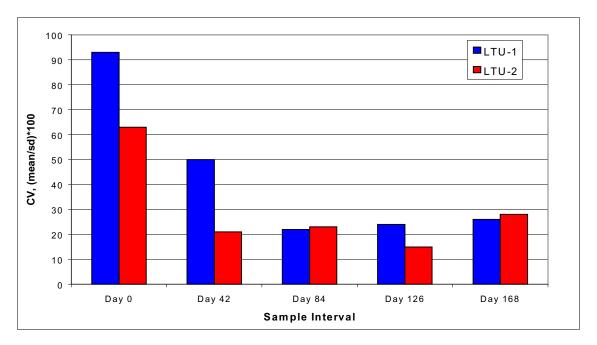

Figure 19. Coefficients of variation for LTU viable microbial biomass

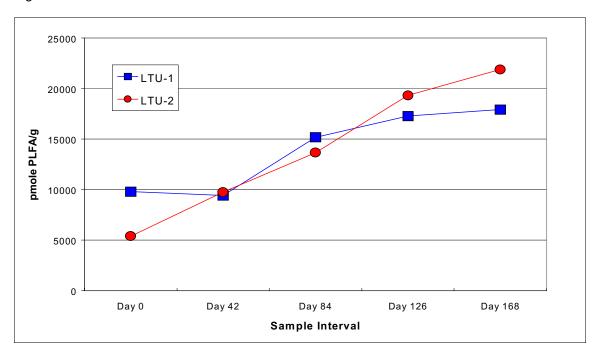

Figure 20. Microbial biomass in LTU 1 and LTU 2

Over the time of the study, both LTUs showed significant increase in the percentages of PLFA that are indicative of Gram-negative bacteria (Figure 21). In contrast, PLFA descriptive of Gram-positive bacteria remained at the Day 0 levels or declined slightly (Figure 22). The Gram-negative increase correlated with the biomass increase in both LTUs (r = 0.777 for LTU 1 and 0.895 for LTU 2). Significant differences between Day 0 and all subsequent time points were measured.

Assuming 1 pmole, PLFA is equivalent to 2.5×104 cells. Coefficient of variation, cv%.

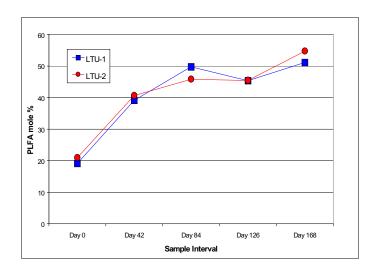

Figure 21. Relative abundance of Gram-negative bacteria

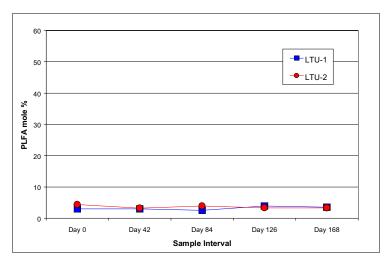

Figure 22. Relative abundance of Gram-positive bacteria

The community composition showed signs of divergence from Day 84 onward. The divergence was first identified by hierarchial cluster analysis. Using the results of this analysis, five of the seven replicate subsamples from each LTU were identified which showed a definable similarity (i.e., all were linked at a euclidean distance of 2.0 or less). PLFA profiles of the five replicate samples are presented in Figure 23 which shows only the Day 168 endpoint analysis, since the community differences identified at Day 84 were also identified at Day 168 with only the magnitude of the divergence changing (i.e., increasing). Six PLFA differed significantly between the two LTUs. Within the ubiquitous PLFA classification, normal saturated 14:0 or myristic acid and 18:0 or stearic acid were identified. Within the Gram-negative classification, two cyclopropyl PLFA (cy17:0 and cy19:0) and two trans monounsaturated PLFA (16:1w7t and 18:1w7t) were identified. Since none of the PLFA within the Gram-positive classification differed significantly between LTUs, it can be assumed that the input of these organisms (Gram-positive) to the overall functioning of the LTUs is negligible. The Gram-negative input was, however, highly significant.

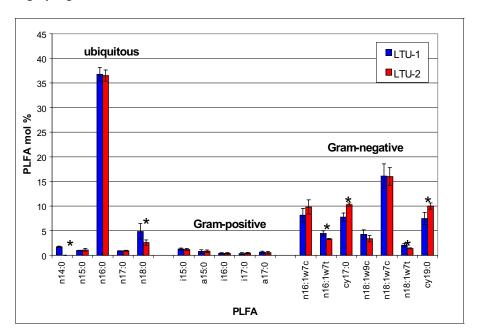

Figure 23. Microbial community composition in both LTUs at Day 168

Increased percentages of myristic and *trans* PLFA in LTU 1 are conducive to the presence of the *Pseudomonas* sp. of bacteria. *Pseudomonas* sp. are consistently isolated from PAH contaminated sites, and a number of species have been demonstrated to have the capacity to mineralize some of these compounds. The increased percentages of cyclopropyl PLFA in LTU 2 is also conducive to the presence of *Pseudomonas* species but reflects a physiological response to changing environmental conditions. In fact, both *trans* and cyclopropyl PLFA are synthesized by Gram-negative bacteria in response to changing environmental conditions, and the divergence seen with the analyses described above likely incorporates this phenomenon as well as any taxonomic differences.

Trans acids have increased in prevalence inside the bacterial membrane in response to toxic exposures. Cyclopropyl PLFA have occurred at different concentrations throughout the bacterial growth phase. Typically, high cyclopropyl PLFA concentrations are taken as a sign of an old and tired Gramnegative bacterial community. To measure the impact of the environment on the formation of these two PLFA classes (trans and cyclopropyl), the respective concentrations must be normalized to a related factor such as the parent compound.

The ratio of 16:1w7(*trans*) to 16:1w7(*cis*), product-to-parent compound, suggests an increasing bacterial response by the indigenous bacteria to the presence of the xenobiotics in the soil. The increased response was significant in both LTUs at all time points, compared to the Day 0 values. Only Day 168 (final) values showed a significant difference between LTUs. These results are consistent with bioslurry microcosm studies where PAH concentrations often exceed initial values by 20 to 30% after a relatively short period of incubation. An increase in the bioavailability of the toxicant would induce an increase in the *trans/cis* ratio.

Cy17:0 is also derived from the parent monounsaturate 16:1w7c, and statisticaly significant increases in this ratio were also observed at all time points (with respect to the Day 0 values). There was, however, no significant difference between the two LTUs at any of the time points. This is interesting, since the total cyclopropyl abundance was greater in LTU 2. This suggests that differences in taxonomy are also a contributing factor to the divergence between LTUs. Nevertheless, the increasing prevalence of cyclopropyl PLFA likely indicates the occurrence of "old age" in at least a portion of the Gram-negative bacterial population. If the microorganisms in the LTUs become stimulated (for example, due to tilling), then nutrient pools (if not supplemented) will become limiting and cell growth will be slowed. Once in the stationary phase of the growth cycle, bacteria, in particular Gram-negative bacteria, will synthesize cyclopropyl PLFA.

Respiration gas analysis

Figures 24 and 26 depict the concentrations of oxygen and carbon dioxide in the soil of LTU 1 and 2, respectively. In both LTUs, the peaks of CO_2 production correspond to O_2 depletion. Especially evident in LTU 2, the trend during the final 2 months of sampling was toward an increase in CO_2 production and a decrease in the soil O_2 concentration. The effects of water, the addition of nitrogen, and the effects of tilling on respiration in LTU 1 and LTU 2 are depicted in Figures 25 and 27, respectively. Cultivation and nitrogen addition both appear to have a positive effect on the production of carbon dioxide.

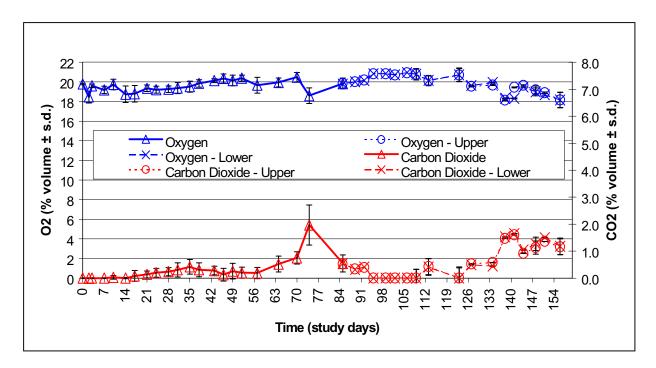

Figure 24. LTU 1. Respiration

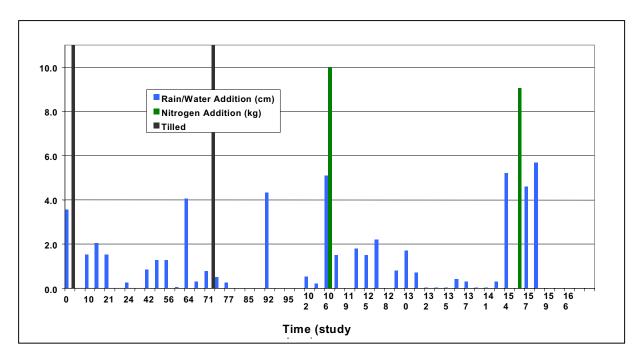

Figure 25. LTU 1. Water and nutrient addition, and tilling

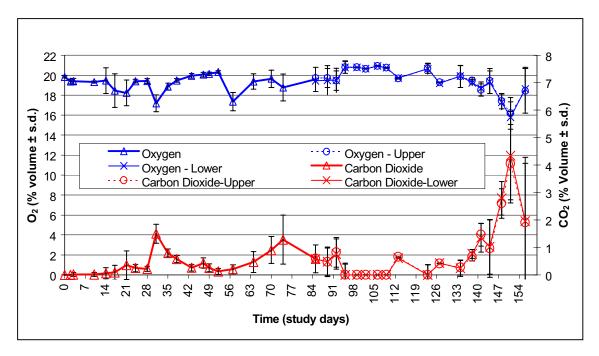

Figure 26. LTU 2. Respiration

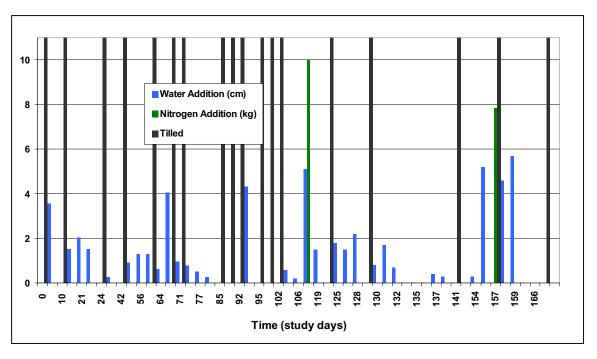

Figure 27. LTU 2. Water and nutrient additions, and tilling

Data Analysis

Contaminant reduction

When the percent reduction from the initial concentration is calculated, they indicate an 8% greater reduction in overall PAH in LTU 2 than LTU 1 (Table 10). This difference is even more apparent when the BaP equivalents are calculated. Then it becomes an 11.3% difference in reduction.

Table 10			
Reduction (%) from In	itial Concentra	tions of PAHs and BaP	
Equivalents			
		% Reduction	
Contaminant	LTU 1	LTU 2	
PAH (overall, avg)	27.21	35.5

Chrysene (4-ring)	19.40	8.31	
Benzo(a)anthracene (4-ring)	22.63	13.76	
Benzo(a)pyrene (5-ring)	10.88	17.85	
Indeno-(1,2,3)-pyrene (6-ring)	17.30	18.86	

Degradation kinetics

The degradation kinetics (Tables 11 and 12) show that, based on zero-order degradation, at the present rate of decrease, it will take 1.69 years to reduce the overall PAH burden of the Popile soil to 5 ppm without treatment (LTU 1). To reach the goal of 5 ppm BaP equivalents, however, will take 9.86 years. For LTU 2, the average PAH reduction will require 1.3 years. The BaP goal, however, will only take 2.79 years.

Degradation of PCP mentioned earlier, discusses the relationship between soil pH and PCP concentration. The PCP concentration in LTU-1 reached a peak after 126 days and then declined throughout the duration of the study (Day 168). In LTU 2, the peak of PCP concentration was attained earlier in the study (at 42 days) and maintained until Day 126, when it began a slow decline. The apparent rise and fall in PCP concentration in the LTUs appears to be an artifact of soil pH changes. The time elapsed between the respective PCP peak concentrations and Day 168 was insufficient to separate artifact from true degradation and attain reliable kinetic data.

6 Summary and Conclusions

Based on the objectives of treatment goals, kinetics, and leaching potential, this study suggests:

- a. ROD treatment goals will not be met using a 6-month lift design in a landfarming system.
- b. ROD treatment goals for BaP may be met by extending the duration of each lift treatment. The duration of the study was too short to demonstrate conclusive biodegradation of PCP.
- c. Cultivation associated with landfarming did not increase the leachability of contaminants in the Popile soil. The leach data supports the groundwater model showing that the contaminant is not moving from the site under these test conditions. However, in time some change could occur that would render the contaminant mobile and it could migrate to the groundwater.

Beyond meeting the stated objectives of the study, the following pertinent observations were made. The high concentration of hydrophobic contaminants inhibited aqueous phase nutrient additions. Slow-release nutrients applied in a solid form should be a more effective method of maintaining appropriate C:N:R: ratios. The increase in microbial biomass and the change in community makeup in LTU 2 by the end of the study suggest biodegradation of the more recalcitrant PAHs, since LTU 2 saw a greater reduction in benzo(a)pyrene and other 4- and 5-ring PAHs. Cultivation had a positive impact on the degradation kinetics shown by the greater overall decrease in contaminant in LTU 2 over LTU 1.

7 Recommendations

The U.S. Engineer Research and Development Center (ERDC) recommends that the U.S. Army Engineer District, New Orleans (USAEDNO), consider continued leveraged funding of Popile, Phase III, pilot-scale activities. The ERDC is the center of the Federal Integrated Biotreatment Research Consortium (FIBRC), a research and development project of the Strategic Environmental Research and Development Project (SERDP). Remediation of PAH-contaminated material is a thrust of FIBRC. Dr. Hap Pritchard, Naval Research Laboratory (NRL), is the Thrust Area Leader. Dr. Pritchard has observed the development of pilot-scale landfarming expertise between ERDC and the USAEDNO. This has resulted in a request for a collaborative continuation between ERDC, FIBRC, and USAEDNO of the Popile study.

The FIBRC plan is to innoculate the treated Popile soil with known PAH-degrading bacteria from NRL. These microorganisms have been isolated and cultured as part of the SERDP-FIBRC effort. The FIBRC will contribute to the cost of this effort.

The benefit to USAEDNO, EPA, and the State of Arkansas, Department of Environmental Quality, is a potential treatment protocol that will meet the ROD goals and further develop an emerging technology consistent with the objectives of the USACE Innovative Technology Advocate Initiative.

13. SUPPLEMENTARY NOTES

14. ABSTRACT

A pilot-scale study of traditional landfarming techniques was conducted to evaluate the treatment requirements directed in the Comprehensive Environmental Remediation Compensation and Liability Act (CERCLA) Record of Decision (ROD) from EPA Region 6 for this site. The study was conducted to: (a) determine if treatment goals specified in the ROD were achievable for site soils (5-ppm benzo(a)pyrene [BaP] equivalents and 3-ppm pentachlorophenol [PCP]; (b) evaluate contaminant degradation kinetics; and (c) evaluate leaching potential of treated soil.

Initial soil characterization (physical, chemical, biological) indicated a clay/silt soil (based on Atterberg limits and particle size distribution) with high contamination (polycyclic aromatic hydrocarbons [PAH] \cong 13,000 ppm, PCP \cong 775 ppm, BaP eq \cong 105 ppm), and an indigenous biological community (approximately 10^7 cells/g as determined by ester linked polar lipid fatty acid (PLFA) analysis). Intermittently scheduled experimental analysis included contaminant concentration, nutrient concentration, pH, moisture, in situ respiration, and microbial community/biomass analysis.

14. ABSTRACT (Concluded)

The pilot-scale site consisted of a modified RCRA secondary containment system that contained two, 3-cu yd land-treatment units (LTUs) designed to simulate field conditions. LTU 1 was cultivated on an oxygen-dependent basis. LTU 2 was cultivated on a fixed schedule. Soil moisture was maintained between 50% and 80% of field moisture capacity. A novel in situ respiration analysis technique was developed using a custom fabricated dry well and an in-line O₂, CO₂, CH₄ analyzer to evaluate aerobic biological activity. Before and after treatment leachability analyses were conducted using the Sequential Batch Leachate Test (SBLT) and the Synthetic Precipitate Leaching Procedure (SPLP) to evaluate the groundwater implications of the underlying aquifer when the treated material is placed back onsite.

Using a zero-order degradation model, contaminant analysis indicated that BaP treatement goals could be met in 9.6 years for LTU 1 and 2.7 years for LTU 2. PCP was not degraded appreciably in either LTU. Respiration analysis, coupled with statistically significant reduction in heavy PAHs (4-, 5-, and 6-ring), demonstrated significant biological activity even at the unusually high contaminant concentrations observed. PLFA analysis showed continuous increase in biomass and divergence of community composition between LTU 1 and LTU 2. LTU 2 showed an increase in the relative percentage of gram negative bacteria. Pre- and postleachability analysis indicates that the treated material will not serve as a source of groundwater contamination if placed back onsite.
